Motivation

Do mid-latitude SSTs affect the atmosphere?

Does extratropical oceanic variability affect climate variability?

- Mid-oceanic thermal fronts, such as the Gulf Stream and Kuroshio Extension, are permanent features of the midlatitude ocean circulation
- The circulation in the atmospheric marine boundary layer (AMBL) adjusts to changes in the oceanic surface conditions within several hours. The AMBL reaches heights of 600-1200m
- We use a hierarchy of models: quasi-geostrophic (QG) BT and BC - and GCM.

We study the flow induced by an East-West oriented SST front of finite zonal extent (600 km). The SST front has the pattern: $T(y) = -T^{*}tanh(y/50 \text{ km})$

The atmospheric model is composed of a steady, analytical AMBL and a time-dependent, QG, baroclinic (BC) model with two modes in the vertical (corresponding to two layers).

The vertical velocity, w, at the top of the AMBL, $H_{\rm E}$

This mechanism spins up an eastward jet in the free atmosphere; see Feliks, Ghil and Simonnet, 2007, J. Atmos. Sci., 64, 97-116.

The evolution of the barotropic mode. Domain (5000 km x 5000 km)

Three kinds of unstable oscillatory modes:

First, antisymmetric instabilities are baroclinic; they have a standing dipole structure. The dominant mode has a period of 270 days.

Second, symmetric instabilities are barotropic and develop at the eastern edge of the eastward jet; this mode was also obtained in an equivalent barotropic model The dominant mode has a period of 30 days: see also Feliks et al., JAS, 2004.

Third, northward-propagating instabilities can be decomposed into two standing parts, an antisymmetric and a symmetric part. The dominant mode has a period of 103 days. The spatio-temporal evolution of this mode resembles the observed 70-day mode of Plaut & Vautard (1994).

Conclusions from the two idealized models

Three kinds of unstable oscillatory modes are obtained:

(3) northward-propagating mode can be decomposed

These effects depend of the atmospheric model's high resolution

The impact of a realistic oceanic thermal front on

the mid-latitude atmosphere over the Gulf Stream

The idealized-model study strongly suggests that the mid-latitude

oceans can influence low-frequency atmospheric variability above

them, provided oceanic fronts like the Gulf Stream and Kuroshio

We use an IPCC-class general circulation model (GCM), LMD-Z,

and a more realistic mean Gulf Stream SST front. The model is

integrated with a high-resolution zoom (hence the 'Z') in the Gulf

Stream area to resolve correctly the effects of the front.

(1) antisymmetric due to baroclinic instability,

(2) symmetric due to barotropic instability, with a period of 30 days;

into an antisymmetric and a symmetric,

with a period of 6-8 months;

with a period of 2-3 months

are sufficiently well resolved spatially.

of 50 km x 50 km!

SST of the standard, low-resolution simulation

A higher resolution, more realistic thermal-front anomaly has been added

The mean horizontal wind between days 100-800 for the lower levels of the troposphere.

The flow diverges over the cold side of the SST front, and converges over its warm side.

Air descending over the cold side results in an cyclonic anomaly; ascent over the warm side results in an anticyclonic anomaly.

Preliminary conclusions

The divergence vs. convergence of the atmospheric flow over the two sides of the SST front obtained in the IPCC- class LMD-Z model and the idealized QG model are very similar.

Low-frequency oscillations with a prominent peak at 50 days were found in the LMD-Z model. This peak was enhanced significantly when the realistic oceanic front was added to the model.

North of latitude 400N Cyclonic flow anomaly (realistic-minusstandard run) found over the cold (western) side of the front and the anticyclonic flow anomaly over the warm (eastern) side
